

Fast Image Classification for Monument Recognition

GIUSEPPE AMATO and FABRIZIO FALCHI and CLAUDIO GENNARO, ISTI-CNR

Content-based image classification is a wide research field addressing also the landmark recognition problem. Among the many classification techniques proposed, the k -nearest neighbor (kNN) is one of the most simple and widely used methods. In this paper, we use kNN classification and landmark recognition techniques to address the problem of monument recognition in images. We propose two novel approaches that exploit kNN classification technique in conjunction with local visual descriptors.

The first approach is based on a relaxed definition of the local feature based image to image similarity and allows standard kNN classification to be efficiently executed with the support of access methods for similarity search.

The second approach uses kNN classification to classify local features, rather than images. An image is classified evaluating the consensus among the classification of its local features. Also in this case access methods for similarity search can be used to make the classification approach efficient.

The proposed strategies were extensively tested and compared against other state of the art alternatives, in a monument and cultural heritage landmark recognition setting. The results proved the superiority of our approaches.

An additional relevant contribution of this paper is the exhaustive comparison of various types of local features and image matching solutions for recognition of monuments and cultural heritage related landmarks.

1. INTRODUCTION

Perhaps the easiest way to obtain information about something is to use a picture of the object of interest as a query. Consider, for instance, a cultural tourist who is in front of a monument and wants to have information about it. A very easy and intuitive action can be that of pointing the monument with a smartphone and obtaining pertinent and contextual information.

The aim of this paper is to discuss, propose and compare techniques of image recognition that can be used to support the scenario above described. The proposed techniques have been thoughtfully tested and compared in a cultural heritage domain.

A commonly-used approach to identify an object contained in a query image is to use the k -nearest-neighbor (kNN) classification algorithm [Cover and Hart 1967]. At the most abstract level, a kNN classifier executes the following steps. Given a query image, the kNN algorithm scans a training set to retrieve the best matching images. The most represented class (if any), among the retrieved images, determines the class of the object contained in the query image.

A promising technique, increasingly applied with success in recent years in image-matching tasks, is to compare images in terms of their local features. *Local features* (or *descriptors*) are visual descriptors of selected interest points, or key points, occurring in images [Lowe 2004; Bay et al. 2006; Rublee et al. 2011]. The comparison of two images, in terms of their local features, involves two steps: the detection of pairs of matching key points in the two images, and a geometric consistency check of the position of these matching key points. Determining the pairs of matching key points in two images involves finding pairs of local features whose mutual similarity is much higher than their similarity with other local features [Lowe 2004]. Checking the geometric consistency of the identified matching pairs implies finding a reasonable geometric transformation that maps the position of most of the matching key points of the first image to the position of the corresponding key points of the second image [Fischler and Bolles 1981]. Using local feature matching and geometric consistency check strategies, it is possible to rank images of a training set according to the degree with which they match the query image, and then execute the kNN classification algorithm.

Other descriptors, such as MSER (Maximally Stable Extremal Region) [Matas et al. 2004] and LBP (Local Binary Pattern) [Ojala et al. 2002] can be used for image-matching tasks. However, according to the reported results in [Mikolajczyk and Schmid 2005; Mikolajczyk et al. 2005] local features similar to the SIFT descriptor generally perform best on object recognition problems. Moreover, the methods such as SIFT (Scale Invariant Feature Transform), SURF (Speed Up Robust Features), and ORB (Oriented FAST and Rotated BRIEF) provide both an interest point detector and a feature descriptor implementation.

The idea of applying the kNN classification in combination with the geometric consistency technique is very effective for tasks where only a few objects need to be recognized and the training sets are small. The drawback of this approach is that it is not scalable when the number of training images used to describe the objects is very large. The execution of the kNN classification algorithm requires that the query image be sequentially compared with all the images of the training set. In order to compare the query image with a single image of the training set, all local features of the query image must be compared with all local features of the training set image. Considering that each image is typically described by thousands of local features, this means that a single image comparison requires something like $1,000 \times 1,000$ local feature comparisons. This has to be repeated for all the images of the training set, every time a new query image is processed.

For example, in the experiments that will be described in this paper, the size of the training set is some orders of magnitude larger than the number of objects (monuments in our case) to be recognized. In fact, a query image related to a monument, for instance a church or a tower, might be taken from an arbitrary position from anywhere around the monument, capturing just portions of the monument and of the landmark in which it is situated. Consequently, for a single monument, we could need hundreds of training images, depicting it from various points of views and perspectives, in order to obtain a high recognition quality. The recognition of small objects poses less problems given that, in many cases, such objects are entirely contained in the query image. In these cases, typically, just the orientation of the objects changes.

In order to reduce the cost of finding the best matches for local image features, some years ago the *bag of visual words (BoW)* [Sivic and Zisserman 2003] paradigm was introduced. With this technique, sometimes called bag of features, groups of very similar local features, taken from the entire training set, are clustered together and represented by their centroid (a representative feature for the entire cluster denoted visual word). The set of centroids is called the *visual word vocabulary*. An image is then represented by quantizing each feature to its nearest visual word. In order to decide whether two local features belonging to two different images match, it is sufficient to check whether they belong to the same cluster, or in other words, are represented by the same visual word.

The *kNN* classification technique can be successfully applied directly to the BoW representation. However, this approach still presents some scalability and effectiveness problems. Even with the use of inverted files to maintain relationships among features and images, “a fundamental difference between an image query (e.g. 1,500 visual terms) and a text query (e.g. 3 terms) is largely ignored in existing index design. This difference makes the inverted list inappropriate to index images” [Zhang et al. 2009]. In addition, the use of the BoW approach makes it difficult to efficiently perform a geometric consistency check, and the approximation introduced by the quantization of the local features reduces the effectiveness.

The approaches presented in this work lie in between these two extremes (direct use of local features, on one side, and BoW on the other). We still exploit the effectiveness of local features and geometric consistency but we rely on the use of access methods for local image features [Zezula et al. 2006; Samet 2005] in order to scale to a large number of classes and training images. These strategies have been tested and compared against other state of the art approaches in the context of landmark recognition for cultural heritage.

2. CONTRIBUTION OF THIS PAPER

In this paper, we compare several strategies to recognize the content of digital pictures against two novel proposed approaches. We particularly focus on discussing and evaluating how the various options and techniques perform in the applicative scenario of monument and cultural heritage related landmark recognition. The two new proposed approaches are based on image *kNN* classification techniques.

The first approach exploits *kNN* classification to classify images and relies on a relaxed definition of the local feature based image to image similarity definition, which allows efficient index for similarity search to be used. Surprisingly, we show that in addition to increasing efficiency and scalability, this approach also increases effectiveness.

The second approach that we propose, called *Local Features Based Image Classifier*, uses *kNN* classification to classify individual local features of an image, rather than the entire image. It consists of a two-step classification process: 1) *kNN* classification of individual local features, and 2) classification of whole images evaluating the consensus among the classes and the confidences assigned to each local feature in step 1). Also this approach makes it possible the use of efficient indexes for similarity search in order to offer high efficiency and scalability, without penalizing effectiveness. Tests were executed using various types of local features, and also applying geometric consistency check techniques.

An additional significant contribution of this paper is the comparison between various types of local feature and image matching solutions in a monument and cultural heritage related landmark recognition scenario. As far as we know, no such complete and extensive comparisons have been performed previously in such a consistent and specific scenario.

A preliminary version of the approaches presented in this paper was presented in [Amato et al. 2011]. The novel contribution here, with respect to previous work, can be summarized as follows. We extensively investigated and experimented different approaches of *kNN* classifications for landmark

recognition, and in particular, we introduced the novel concept of “local feature based image classification”. We compared the proposed approaches using ORB and BRISK features, in addition to SIFT and SURF features. We also compared our results against the BoW approach. Finally, we introduced the use of a geometric constraint check in combination with the local feature based image classifier. More experiments and analysis were also carried-out.

The paper is organized as follows. Section 3 presents other related work. Section 4 provides the background for the remaining of the paper. Section 5 introduces the pairwise distance criterion used in classification algorithms. Sections 6 contains the details of our proposed approaches and Section 7 validates our proposed techniques. A concluding summary is given in Section 8.

3. RELATED WORK

In this paper, we address the problem of landmark recognition and visual categorization with special focus on kNN classification and local image features. In [Chen et al. 2009] a survey of the literature on mobile landmark recognition for information retrieval is given. The classification methods reported include SVM, Adaboost, Bayesian model, HMM, GMM. However, the survey does not report the kNN classification technique, which is the main focus of this paper.

In [Zheng et al. 2009], Google presented its approach to building a web-scale landmark recognition engine. Most of the work reported was used to implement the Google Goggles service [goo 2010]. The image recognition is based on a kNN classifier using local feature matching. According to the authors, the recognition performance on over 5,000 landmarks reaches an accuracy of 80.8%.

Popescu et al. [Popescu and Moëllic 2009] used a geo-referenced collection of 5,000 landmarks worldwide to automatically annotate landmark images. They organized the landmarks spatially and classified the images using spatial distance together with kNN classification. The images to label are indexed using only the BoW approach.

A mobile landmark recognition system called Snap2Tell were developed in [Chevallet et al. 2007]. However, the authors use a simple matching technique based on color histograms and a $1NN$ classifier, combined with localization information. For the task of image-based geolocation, a similar approach has been exploited in [Hays and Efros 2008].

In [Labb 2014] a tutorial on how a system for object recognition can also be used for place recognition is given. The system uses local features to execute the recognition task.

In [Fagni et al. 2010], various MPEG-7 global descriptors have been used to build kNN classifier committees. However, local features were not taken in consideration.

Boiman et al. [Boiman et al. 2008] propose an approach to $1NN$ image classification that uses a kd-tree structure for efficiency and is very similar in spirit to one of the approaches presented in this paper. This work also introduced a novel, non-parametric approach for image classification, the *Naive Bayes Nearest Neighbor classifier* (NBNN), which was further generalized by Timofte et al [Timofte et al. 2013] by replacing the nearest neighbor part with more elaborate and robust (sparse) representations (kNN , Iterative Nearest Neighbors (INN), Local Linear Embedding (LLE), etc.). Bosch et al. [Bosch et al. 2008] also use a kNN classifier in combination probabilistic Latent Semantic Analysis for scene classification purposes. However, no access methods were used to handle efficiency issues in the case of large dimension problems.

kNN classifiers are also suitable for real-time learning applications such as 3D object tracking. In [Hinterstoisser et al. 2011], the authors exploit a simple nearest neighbors classification using a set of “mean patches” that encode the average of the keypoints appearing over a limited set of poses. However, learning approaches do not scale very well with respect to the size of the keypoints database [Lourenço 2011].

[Johns and Yang 2011] addresses the problem of recognizing a place depicted in an image by clustering similar database images to represent distinct scenes, and tracking local features that are consistently detected to form a set of real-world landmarks. In this work, features are first quantized and images are described as a BoW, allowing a more efficient means of computing image similarities. The closest k database images to the query image are then passed on to the second stage. Here, geometric verification prunes out false positive feature matches from the first stage.

The idea of applying the BoW technique to transform images described by local features in vectors to exploit kNN classification is also used in [Mejdoub and Ben Amar 2011]. In this study, the authors propose a new categorization tree based on the kNN algorithm. The proposed categorization tree combines both unsupervised and supervised classification of local feature vectors. The advantage of this tree is that it achieves a trade-off between accuracy and speed-up of categorization. The proposed technique, however, involves several complex steps: a hierarchical lattice vector quantization algorithm, and a supervised step based on both feature vector labeling and a supervised feature selection method. In this respect, similar approaches in which high dimensional descriptors based on local features, such as Vector of Locally Aggregated Descriptors (VLAD) [Jegou et al. 2010] and Locality constraint Linear Coding (LLC) [Wang et al. 2010], are employed have become a topic of considerable interest in the development of classification systems (see for instance [Su et al. 2013; Amato et al. 2013; Perronnin and Dance 2007]).

In [Haase and Denzler 2011], state-of-the-art CBIR methods were tested in order to recognize landmarks in a large-scale scenario. The image dataset consists of 900 landmarks from 449 cities and 228 countries. BoW and visual phrase approaches were tested in combination with *SVM* and kNN classifiers. The best results were obtained by using a kNN classifier in combination with the BoW description.

Some approaches exploit a metric learning phase to improve the performance of metric-based kNN classification algorithms. Although these methods are reported to be effective, most of the existing applications are still limited to vector space models in which there is no connection to local features. For a recent survey on metric learning, see [Bellet et al. 2013]. Within this topic, there is increased interest in local distance functions for nearest neighbor classification on local image patches [Mahamud and Hebert 2003] or geometric blur features [Frome et al. 2007; Malisiewicz and Efros 2008; Zhang et al. 2006; Zhang et al. 2011]. Note that such approaches, however, often map local features to multi-resolution histograms and compute a weighted histogram intersection; approximate correspondence can be captured by a pyramid vector representation [Grauman and Darrell 2007].

Weighted voting is another common approach for improving kNN classifiers. Weights are usually either based on the position of an element in the kNN list or its distance to the observed data point [Zuo et al. 2008]. However, the hubness weighting scheme which was first proposed for high-dimensional data in [Radovanović] is slightly more flexible; each point in the training set has a unique associated weight, with which it votes whenever it appears in some kNN list, regardless of its position in the list. This idea was recently generalized into fuzzy kNN for local features [Tomašev and Radovanović]. This technique still relies on vector representation and therefore is only suitable for high-dimensional data such as codebooks of most representative SIFT features (BoW).

Finally, comparatively few papers have proposed the use of boosting techniques for kNN classification. Boosting methods adaptively change the distribution of the training set based on the performance of the previous classifiers [Garca-Pedrajas and Ortiz-Boyer 2009]. Unfortunately, to the best of our knowledge, all boosting techniques for kNN classification rely on a pairwise distance between objects to be classified. A good survey of kNN classification boosting can be found in [Piro et al. 2013].

4. OBJECT RECOGNITION

In this section, we provide preliminaries and give a brief overview of the local features that we have used.

4.1 Notation and Preliminaries

Throughout the paper, we represent each image I by a set of n local features l , i.e. $I = \{l_1, \dots, l_n\}$. With a slight abuse of notation, we use the general notation $d()$ to denote the distance functions used for comparing images or local features.

Let S be a database of objects x and a d distance function for the objects, the k -th nearest neighbor of object q can then be recursively defined as:

$$NN_k(q, S) = \begin{cases} x \in S \mid \forall y \in S \ d(q, y) \geq d(q, x) & \text{if } k = 1; \\ NN_{k-1}(q, S \setminus \{NN_{k-1}(q, S)\}) & \text{if } k > 1. \end{cases} \quad (1)$$

The set of the first k nearest neighbors is defined as:

$$kNN(q, S) = \{NN_{\hat{k}}(q, S) \mid \hat{k} = 1..k\} \quad (2)$$

4.2 Local Features

In the last decade, the introduction of local features to describe image visual content, along with local feature matching and geometric consistency check approaches has significantly advanced the performance of image content and object recognition techniques. In the following, we introduce these two strategies, which are at the basis of the classification techniques that we use to perform the recognition of monuments in images.

Local feature descriptors describe selected individual points or areas in an image. The extraction is executed in two steps. First, a set of keypoints in the image is detected. Second, the area around the selected keypoints is analyzed to extract a visual description. Keypoint selection strategies are appropriately designed to guarantee invariance to scale changes and the same points are selected under different views of the same object. Local feature descriptors contain information that allow local feature matching, i.e. deciding that two local features from two different images represent the same point. Standard information on the position in the image, the orientation and size of the region are typically associated with the visual information that depends on the particular local features. Various local features have been proposed. In this work, we tested SIFT, SURF, ORB, and BRISK.

4.2.1 SIFT. The Scale Invariant Feature Transformation (SIFT) [Lowe 2004] is a representation of low level image content that is based on a transformation of the image data into scale-invariant coordinates relative to local features. Local features are low level descriptions of keypoints in an image. Keypoints are interest points in an image that are invariant to scale and orientation. Keypoints are selected by choosing the most stable points from a set of candidate locations. Each keypoint in an image is associated with one or more orientations, based on local image gradients. Image matching is performed by comparing descriptions of the keypoints in the images.

This extraction scheme has been used by many other local features including the following ones. In particular, SIFT selects keypoints using a difference of gaussians approach that can be seen as an approximation to the Laplacian that results in detecting blobs. The description of each keypoint and its neighbors (i.e., the blob) is based on an histogram of orientation gradients normalized with respect to the dominant orientations in order to be rotation invariant. We used publicly available software developed by David Lowe [sif 2005] to both detect keypoints and extract the SIFT features.

4.2.2 SURF. The basic idea of Speeded Up Robust Features (SURF) [Bay et al. 2006] is quite similar to SIFT. SURF detects some keypoints in an image and describes them using orientation information. However, the SURF definition uses a new method for both the detection of keypoints and their description that is much faster while still guaranteeing a performance comparable to or even better than SIFT. Specifically, keypoint detection relies on a technique based on an approximation of the Hessian Matrix. The descriptor of a keypoint is built considering the distortion of Haar-wavelet responses around the keypoint itself. We used the publicly available noncommercial software developed by the authors [sur 2006] to both detect the keypoints and to extract the SURF features.

4.2.3 ORB. ORB [Rublee et al. 2011] stands for Oriented FAST and Rotated BRIEF. It is a very fast and effective local feature descriptor that selects keypoints using the FAST detector and builds features with an improved version of the BRIEF descriptors that offer rotational invariance. It is very fast in both the feature extraction phases and matching phases, which can be used for real-time applications even with low-power devices and without GPU acceleration. The descriptor has a binary format and the simple Hamming distance is used for comparing local features.

4.2.4 BRISK. Similarly to ORB, BRISK [Leutenegger et al. 2011] is also a binary local feature descriptor. It uses a FAST based keypoint detector and generates a bit-string descriptor from intensity comparisons retrieved by dedicated sampling of keypoint neighborhood. BRISK also uses the Hamming distance to compare local features. A comparison of ORB and BRISK together with BRIEF has been presented in [Heinly et al. 2012].

4.3 Local Features Matching

Local features l automatically extracted from an image I are used to identify, in two distinct images I_i and I_j , couples of matching descriptors (l_i, l_j) where $l_i \in I_i$ and $l_j \in I_j$. Identifying matches requires: comparing local descriptors using a distance function d ; identifying a candidate match $l_j \in I_j$ for any $l_i \in I_i$; filtering out matches with high probability to be incorrect.

For SIFT and SURF the Euclidean distance is used, while the Hamming distance is the obvious choice for binary features such as ORB and BRISK.

The candidate match for l_i is typically the nearest local descriptor in I_j , i.e. $NN_1(l_i, I_j)$.

Filtering incorrect matches is the most difficult task. Lowe showed in [Lowe 2004] that the distance $d(l_i, NN_1(l_i, I_j))$ is not a good measure of the quality of matches. Instead, he proposed to consider the ratio between the distance from l_i of the first and the second nearest neighbors in I_j , i.e.:

$$\sigma(l_i, I_j) = \frac{d(l_i, NN_1(l_i, I_j))}{d(l_i, NN_2(l_i, I_j))} \quad (3)$$

Any matching pair of descriptors $(l_i, NN_1(l_i, I_j))$, $l_i \in I_i$ for which $\sigma(l_i, I_j) > c$, where c is a predefined threshold is discarded. Thus, the set of candidate features between image I_i and I_j is:

$$M_\sigma(I_i, I_j) = \{(l_i, NN_1(l_i, I_j)) \mid \sigma(l_i, I_j) < c, l_i \in I_i\} \quad (4)$$

In [Lowe 2004] it was reported that $c = 0.8$ allows us to eliminate 90% of the false matches while discarding less than 5% of the correct matches when using SIFT. In [Amato and Falchi 2010], an experimental evaluation of classification effectiveness varying c for both SIFT and SURF confirmed the results obtained by Lowe. In the following, we will use $c = 0.8$ for both SIFT and SURF; we used $c = 0.9$ for the ORB and BRISK binary local features because it gave better performance.

We call the set of matches M_σ , defined above, as the *plain distance ratio matches*. In the following we will also define additional strategies to find the set matches, some of which are obtained starting from M_σ itself.

5. PAIRWISE IMAGE DISTANCE

Central to the concept of the kNN classifier is the definition of a pairwise image distance d between two images, which is based on how many features match and how close the matches are.

We define a distance function based on the plain distance ratio matches (5.1), on the BoW quantization approach (5.2), finally we extend the distance functions to also handle geometric consistency checks (5.3 and 5.4).

5.1 Local Feature Matching

The pairwise matching between two images is based on how many of the feature descriptors match. Given a set $M_\sigma(I_i, I_j)$ of candidate local feature matches (see Section 4.3) between two images I_i, I_j , we define the distance as:

$$d_\sigma(I_i, I_j) = 1 - \frac{|M_\sigma(I_i, I_j)|}{|I_i|} \quad (5)$$

Note that the proposed distance measure is not actually a distance measure since it is not symmetric: $d_\sigma(I_i, I_j) \neq d_\sigma(I_j, I_i)$. Moreover, since $0 \leq d_\sigma \leq 1$, sometimes it is more convenient to use the concept of *similarity* $s_\sigma = 1 - d_\sigma$.

5.2 Bag of Words Matching

The traditional BoW model used for text, has been applied to images by treating image features as words. As for text documents, a BoW description is a sparse vector of number of occurrences of visual words, taken from a predefined vocabulary. The assumption is that two features match if they have been assigned to the very same visual words. Thus, the BoW approach can also be used for efficient features matching (see [Philbin et al. 2007; Philbin 2010]).

The first step to describe images using visual words is to select some local features creating the *visual vocabulary*. The visual vocabulary is typically built grouping local descriptors of the dataset using a clustering algorithm such as k -means. The second step consists of describing each image using the words of the vocabulary that occur in it.

At the end of the process, each image is described as a set of visual words. More formally, the BoW framework consists of a group of cluster centers, referred to as visual words $W = \{w_1, w_2, \dots, w_k\}$ [Turcot and Lowe 2009]. Let b_W be a function that assigns a visual word to each local descriptor l_i of an image I_i , as follows:

$$b_W(l_i) = \arg_w NN_1(l_i, W) \quad (6)$$

Let $B_W(I_i)$ be the set of visual words corresponding to the local features of the image I_i , i.e.:

$$B_W(I_i) = \{b_W(l_i) \mid \forall l_i \in I_i\}, \quad (7)$$

we are able to convert images into a vector of visual word occurrences, as for standard full-text retrieval term frequency (TF) approach:

$$tf_j(I_i) = |\{j\} \cap B_W(I_i)| \quad (8)$$

where $tf_m(I_i)$ is the m -th element of the vector of visual words and corresponds to the number of occurrences of w_m in the set $B_W(I_i)$. In order to compare image word occurrence, cosine similarity can be used:

$$d_w(I_i, I_j) = 1 - \frac{\sum_{m=1}^n tf_m(I_i)tf_m(I_j)}{\sqrt{\sum_{m=1}^n tf_m(I_i)^2} \sqrt{\sum_{m=1}^n tf_m(I_j)^2}} \quad (9)$$

More advanced weighting schemes based on Information Retrieval technology such as TF-IDF can be used (e.g. [Tirilly et al. 2010]). Using these similarity functions, traditional inverted files can be used to search nearest neighbor images.

5.3 Geometric Consistency Constraints

In order to further improve the effectiveness of the pairwise image matching described above, geometric consistency constraints can be exploited. The problem is to determine a transformation that maps the positions of the keypoints in the first image to the positions of the corresponding keypoints of the second image. Only matches consistent with this transformation are retained. As discussed previously, the coordinates of the keypoints, together with the size and orientation of the region, are associated with each local descriptor.

The algorithms used to estimate such a transformation are typically the Random Sample Consensus (RANSAC) [Fischler and Bolles 1981] and Least Median of Squares. However, fitting methods such as RANSAC or Least Median of Squares perform poorly when the percent of correct matches falls much below 50%. Fortunately, much better performance can be obtained by clustering features in the scale and orientation space using the Hough transform as suggested in [Lowe 2004].

Estimating a transformation using RANSAC involves: 1) random selecting the requested number of matches for the given transformation estimation; 2) evaluating the transformation itself; and 3) selecting the matches that are consistency with it.

A geometric transformation maps a point $\vec{p} = (p_x, p_y)$ to a second point $\vec{p}' = (p'_x, p'_y)$. In the following, we report the most common types of transformations that can be searched.

Each of the following transformations can be used as a filter for a set of candidate matches M . In fact, the subset of matches that are consistent with the evaluated transformation is presumed to be a more reliable set of candidate matches with respect to the original M .

5.3.1 Hough Transform (\mathcal{F}_{HOU}). Hough Transform is used to cluster matches into groups that agree upon a particular model pose (intuitively, the same point of view description of an object). Hough Transform identifies clusters of features with a consistent interpretation by using each feature to vote for all object poses that are consistent with the feature [Lowe 2004]. When clusters of features are found that vote for the same pose of an object, the probability of the interpretation being correct is much higher than for any single feature. In our experiments, we create a Hough transform entry predicting the model orientation, and scale from the match hypothesis. A pseudo-random hash function is used to insert votes into a one-dimensional hash table in which collisions are easily detected. The Hough transform is typically used to increase the percentage of inliers before estimating a transformation (typically using RANSAC). However, the greater cluster can be considered to be the subset of most relevant matches.

Therefore, we define $\mathcal{F}_{HOU}(M)$ as the subset of candidate matches M that belongs to the greater cluster obtained with the Hough transform. For our experiments, we used the same parameters proposed in [Lowe 2004], i.e. bin size of 30 degrees for orientation, a factor of 2 for scale, and 0.25 times the maximum model dimension for location.

Considering the clusters of matches created by the Hough transform, it is possible to estimate a transformation that can map the points of one image onto another.

5.3.2 *RST* (\mathcal{F}_{RST}). Rotation, Scale and Translation transformation can be formalized as follows:

$$\begin{bmatrix} p'_x \\ p'_y \end{bmatrix} = \begin{bmatrix} s * \cos(\theta) & -\sin(\theta) \\ \sin(\theta) & s * \cos(\theta) \end{bmatrix} \begin{bmatrix} p_x \\ p_y \end{bmatrix} + \begin{bmatrix} t_x \\ t_y \end{bmatrix} \quad (10)$$

where θ is the angle of the counter clock rotation, s is the scaling and \vec{t} is the translation. Estimating this transformation requires two pairs of matching points (\vec{p} and \vec{p}').

5.3.3 *Affine* (\mathcal{F}_{AFF}). Affine transformation is a linear transformation (rotation, scaling, reflection and shear) followed by a translation.

$$\begin{bmatrix} p'_x \\ p'_y \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} p_x \\ p_y \end{bmatrix} + \begin{bmatrix} t_x \\ t_y \end{bmatrix} \quad (11)$$

Note that an RST transformation is a special case of a general affine transformation. Affine transformation allows one shear mapping and/or reflection in addition to translation, rotation and scaling [Prince 2012]. A shear transformation leaves all points on one axis fixed, while the other points are shifted parallel to the axis by a distance proportional to their perpendicular distance from that axis. Estimating an affine transformation requires three pairs of matching points.

5.3.4 *Homography* (\mathcal{F}_{HMG}). Homography is an invertible projective transformation from the real projective plane to the projective plane that maps lines to straight lines. Any two images in the same planar surface in space are related by a homography.

$$w \begin{bmatrix} p'_x \\ p'_y \\ 1 \end{bmatrix} = \begin{bmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ h_{31} & h_{32} & h_{33} \end{bmatrix} \begin{bmatrix} p_x \\ p_y \\ 1 \end{bmatrix} \quad (12)$$

where w is a scale parameter. Please note that an affine transformation is a special type of general homography whose last row is fixed to $h_{31} = 0, h_{32} = 0, h_{33} = 1$. Estimating this transformation requires four pairs of matching points.

5.3.5 *Isotropic scaling*. Typically, the coordinates of the points of the local features extraction algorithms are reported in pixels of the image. However, a normalization can improve the effectiveness of the transformation estimation. In this work, we use an isotropic scaling [Hartley 1995] that scales and translates the pixel coordinates so as to bring the centroid of the set to the origin, and the average distance from the centroid to $\sqrt{2}$.

5.4 Enhancing Pairwise Image Matching with Geometric Consistency Constraint

Geometric consistency checks can be used when comparing two images still using image distance defined in 5, and by replacing M_σ , with the matches remaining after geometric filtering described above.

In the following we give five options for defining the set of candidate matches M , using M_σ defined in Section 4.3, and the filtering criteria defined in Section 5.3. Used in conjunction with Eq. (5), these options result in five similarity functions. Specifically, the five different instantiations for M are:

- Plain distance ratio matches M_σ
- Hough matches $M_{HOU} = \mathcal{F}_{HOU}(M_\sigma)$
- RST matches $M_{RST} = \mathcal{F}_{RST}(M_\sigma)$
- Affine matches $M_{AFF} = \mathcal{F}_{AFF}(M_\sigma)$

—Homography matches $M_{HMG} = \mathcal{F}_{HMG}(M_\sigma)$

The performance of these similarity functions will be also compared in Section 7 below.

The BoW approach can also be exploited to define a set of candidate matches that can be used as a basis for the geometric consistency checks. In this scenario, we do not use the cosine distance to calculate similarities between vectors; we directly match the BoW components:

$$\dot{M}(I_i, I_j) = \{\langle l_i, l_j \rangle \mid b_w(l_i) = b_w(l_j)\} \quad (13)$$

In this case, \dot{M} is used in place of M_σ , employed in the previous section. Similarly as before, we define four sets of candidate matches that are obtained by filtering the set \dot{M} obtained through the BoW approach.

Thus, in our experiments, in addition to cosine TF and cosine TF-IDF, we test the following BoW based approach:

—Hough matches $\dot{M}_{HOU} = \mathcal{F}_{HOU}(\dot{M})$

—RST matches $\dot{M}_{RST} = \mathcal{F}_{RST}(\dot{M})$

—Affine matches $\dot{M}_{AFF} = \mathcal{F}_{AFF}(\dot{M})$

—Homography matches $\dot{M}_{HMG} = \mathcal{F}_{HMG}(\dot{M})$

6. KNN IMAGE CLASSIFICATION

Document classification has two flavours as single label and multi label. In the single label classification, documents may belong to only one class while in the multi label one, documents may belong to more than one class [Korde and Mahender 2012]. In this paper we only consider single label document classification.

Let S be a database of objects x , d the distance function for the objects, let us have a predefined a predefined set of *classes* (also known as *labels*, or *categories*) $C = \{c_1, \dots, c_m\}$, *Single-label document classification* [Dudani 1975] is the task of automatically approximating or estimating, by means of a function $\hat{\Phi} : S \rightarrow C$, called the *classifier*, an unknown *target function* $\Phi : S \rightarrow C$, that defines how documents ought to be classified.

6.1 The Single Label kNN Classification

The *single-label distance-weighted kNN classifier* is one of the most simple and widely used methods for semi-supervised learning. It first executes a *kNN* search between the objects of the *training set* T . The training set is the subset $T \subset S$ of data used to fit the classifier, and for which we know the target function Φ . The result of this operation is the set $kNN(x, T)$ of labeled documents belonging to the training set, ordered with respect to the increasing values of the distance function d . The label assigned to the object x by the classifier is the class $c_j \in C$ that maximizes the sum of a similarity between x and the documents labeled c_j , in the ranked list $kNN(x, T)$. The similarity between two objects can be calculated as $s = 1 - d$ since, without loss of generality, we assume that $0 \leq d \leq 1$ always holds true. The classification task starts by computing the score $z^k(x, c_j)$ for each label $c_j \in C$:

$$z_s^k(x, c_j) = \sum_{y \in kNN(x, T) : \Phi(y) = c_j} s(x, y) . \quad (14)$$

the class that obtains the maximum score is then chosen:

$$\hat{\Phi}_s^k(x, T) = \arg \max_{c_j \in C} z_s^k(x, c_j) \quad (15)$$

where $\hat{\Phi}_s^k(x, T)$ is the *classification function*. All the *kNN* classifier algorithms that we present in the next sections share the same basic principle and hence the same classification function. They differ in the way that the confidence of the classification is computed and can be used to decide whether the predicted label has a high probability to be correct. A special case is the local features based classification, which uses *kNN* classification for the individual local fractures, to estimate the confidence of the whole image classification.

6.2 Similarity Based kNN Image Classification

This section discusses how to classify images using a *kNN* classifier relying on pairwise image distances as seen in Section 5. The techniques defined in this section is the baseline approach to image classification using local feature.

This approach, along with approach based on BoW, will be compared against the our proposed methods discussed in Sections 6.3 and 6.4.

Given a set of images \mathcal{I} and a predefined set of *classes* $C = \{c_1, \dots, c_m\}$, the *kNN* classification can be obtained with the function: $\hat{\Phi}_s^k(I_i, \mathcal{I})$ defined in Eq. (15), in which in place of the similarity $s = 1 - d$, we can exploit one of the pairwise image distances defined in Section 5. A typical way of evaluating the confidence is 1 minus the ratio between the *score* obtained by the second-best label and the best label, i.e.:

$$\nu_{doc}(\hat{\Phi}_s^k, I_i) = 1 - \frac{\arg \max_{c_j \in C \setminus \{\hat{\Phi}_s^k(I_i)\}} z^k(I_i, c_j)}{\arg \max_{c_j \in C} z^k(I_i, c_j)} .$$

This classification confidence can be used to decide whether the predicted label has a high probability to be correct. A value of ν close to one denotes a high confidence.

When the number of classes, and consequently the number of training images, are large, the use of the simple distance based on local feature matching presented in Section 5.1 becomes prohibitive in terms of efficiency since it implies the sequential scan of the entire training set. In this case, it is useful to introduce some approximations that allow the problem to be more efficiently managed. A widely used solution is that of using the BoW approach presented in Sections 5.2.

As already stated this is just a baseline method to image classification. In next section we will propose a new solution that selects just the most promising local feature pairs in images to be matched. This approach can use indexes for efficient similarity search to speed up the classification process. Surprisingly this method is more efficient and more effective as well, even if just a subset of the local features in images are matched. We call this approach *Dataset Matching*, since the set of promising pairs are selected by submitting similarity queries on the entire database of local features.

6.3 Dataset Matching

The distance measure defined in Section 5.1 is a direct application of the techniques developed by the Computer Vision community and requires the direct comparison of each pair of images. In fact, the distances are neither metric nor symmetric and the complexity of the distance evaluation prevents the use of any sort of indexing. Therefore, given a query, searching for the *k* nearest images to a given query image requires a complete sequential scan of the archive.

On the other hand, the BoW approach makes the search process much faster than when executing a sequential scan of the training set. However, the quantization introduced by the visual vocabulary reduces the effectiveness of the method.

In this respect, we propose an efficient pairwise image matching that relies on access methods for metric space [Zezula et al. 2006], and at the same time increase the effectiveness, even with respect to the approach discussed in Section 5.1.

Let I_i be the image that we want to classify and $S = \{I_1, \dots, I_M\}$ the entire training set of images of size M . We propose to retrieve, for every local feature l_i of I_i the \bar{k} closest local features from the union Ω of all the local features in all the images of the training set $\Omega = \cup_i I_i$. We denote the \bar{k} closest local features to l_i as $\bar{k}NN(l_i, \Omega)$, and we call it the set of *candidate matches*.

Since the distance d functions for comparing local features are metric distances (SIFT and SURF use Euclidian distance, ORB and BRISK use Hamming distance), metric [Zezula et al. 2006] or spatial [Samet 2005] access methods can be used to efficiently execute $\bar{k}NN(l_i, \Omega)$.

We define the matches between an image I_i and any $I_j \in S$ as:

$$\bar{M}(I_i, I_j) = \{\langle l_i, l_j \rangle | l_i \in I_i \wedge l_j = NN_1(l_i, \bar{k}NN(l_i, \Omega) \cap I_j)\} \quad (16)$$

In short, we select the matching local features in two images, just considering the candidate matching local features obtained executing the nearest neighbor similarity search query $\bar{k}NN(l_i, \Omega)$. Note that $\bar{k}NN(l_i, \Omega)$ need to be executed just once for every local feature l_i of I_i independently of the size M of the training set.

In this scenario, \bar{M} is used in place of the candidate set of matches M_σ , employed in Section 5.1 for evaluating the distance between two images:

$$d_S(I_i, I_j) = 1 - \frac{|\bar{M}(I_i, I_j)|}{|I_i|} \quad (17)$$

The matching function \bar{M} , defined in this section, can also be enhanced by the use of the four geometric filtering criteria, defined in Section 5.4. Thus, in Section 7 we also test:

- Plain nearest Neighbor matches \bar{M}
- Hough matches $\bar{M}_{HOU} = \mathcal{F}_{HOU}(\bar{M})$
- RST matches $\bar{M}_{RST} = \mathcal{F}_{RST}(\bar{M})$
- Affine matches $\bar{M}_{AFF} = \mathcal{F}_{AFF}(\bar{M})$
- Homography matches $\bar{M}_{HMG} = \mathcal{F}_{HMG}(\bar{M})$

6.4 Local Features Based kNN Classifier

In the previous section, we considered the classification of an image I_i as a process of retrieving the most similar images in the *training set* \mathcal{T}_i and then applying a kNN classification technique in order to predict the class of I_i .

In this section, we propose a different approach that classifies an image I_i in two steps:

- (1) each local feature $l_i \in I_i$ is first individually classified considering the local features of all the images in the training set \mathcal{T}_i ;
- (2) the whole image is classified considering the class assigned to each local feature and the confidence of the classification evaluated in step 1.

Note that by classifying the local features individually, i.e. before assigning a label to an image, we might lose the implicit mutual information between the interest points of an image. However, surprisingly, we will see that this method gives a better performance than the other approaches.

In the next sections, we will define four distinct algorithms for local feature classification, i.e. step 1. All the proposed algorithms require searching for similar local features for each of the local features belonging to the image.

6.4.1 Step 1: Local Feature Classification. All the following kNN Local Feature Classifiers are applications of the single label distance weighted kNN discussed in Section 6.1. They make use of a similarity function that can be obtained from the distance measure d between local features by applying the well-known transformation $s = 1 - d/d_{MAX}$.

1NN LF Classifier ($\hat{\Phi}^1$). The simplest way to classify a local feature is to consider the label of its closest neighbor in \mathcal{T}_l . The *1NN Local Features Classifier* $\hat{\Phi}_s^1(l_x)$ assigns the label of the closest neighbor in \mathcal{T}_l to a local feature l_x . The confidence of the classification assigned is the similarity between l_i and its nearest neighbor. Formally:

$$\nu(\hat{\Phi}_s^1, l_x) = s(l_x, NN_1(l_x, \mathcal{T}_l))$$

Please note that this classifier does not require any parameter to be set. Moreover, the similarity search over the local features training set is a simple *1NN* search.

Weighted kNN LF Classifier ($\hat{\Phi}^k$). The *Weighted kNN LF Classifier* is the natural application of the kNN classification function $\hat{\Phi}_s^k(l_x, \mathcal{T}_l)$ on local features. The confidence is similarly based on the ratio between second best and best class as follows:

$$\nu(\hat{\Phi}_s^k, l_x) = 1 - \frac{\arg \max_{c_j \in C \setminus \{\hat{\Phi}_s^k(l_x, \mathcal{T}_l)\}} z_s^k(l_x, c_j)}{\arg \max_{c_i \in C} z_s^k(l_x, c_i)}$$

Note that for $k = 1$, we degenerate to the *1NN LF classifier* case, while the measure of confidence is different. In fact, *1NN* always assigns 1 as confidence when $k = 1$, while the kNN LF Classifier considers the first nearest neighbor similarity as measure of confidence. This classifier requires parameter k to be chosen.

LF Matching Classifier ($\hat{\Phi}^m$). The *LF Matching Classifier* decides the candidate label similarly to the *1NN LF Classifier*, i.e., $\hat{\Phi}_s^1(l_x, \mathcal{T}_l)$, while the confidence value of the selected label is evaluated using the idea of the distance ratio discussed in Section 4.3:

$$\nu(\hat{\Phi}_s^1, l_x) = \begin{cases} 1 & \text{if } \dot{\sigma}(l_x, \mathcal{T}_l) < c \\ 0 & \text{otherwise} \end{cases}$$

The distance ratio $\dot{\sigma}$ is computed considering the nearest local feature to l_x and the closest local feature that has a label different from the nearest local feature. Following the idea of Lowe explained in Section 4.3, we define the similarity ratio $\dot{\sigma}$ as:

$$\dot{\sigma}(l_x, \mathcal{T}_l) = \frac{d(l_x, NN_1(l_x, \mathcal{T}_l))}{d(l_x, NN_2^*(l_x, \mathcal{T}_l))}$$

where $NN_2^*(l_x, \mathcal{T}_l)$ is the closest neighbor that is known to be labeled differently than the first.

Note that searching for $NN_2^*(l_x, \mathcal{T}_l)$ cannot be directly translated into a standard kNN search. However, the kNN implementation in metric spaces is generally performed starting with an infinite range and reducing this during the evaluation, considering at any time the current NN_k . The same approach can be used for searching $NN_2^*(l_x, \mathcal{T}_l)$. In fact, while k is not known in advance, the current NN_2^* during the similarity search, can be used to reduce the range of the query. Thus, the similarity search needed for the evaluation of $\dot{\sigma}(l_x, \mathcal{T}_l)$ can be implemented slightly modifying the standard algorithms developed for metric spaces (see [Zezula et al. 2006]).

Parameter c used in the definition of the confidence is equivalent to that used in [Lowe 2004] and [Bay et al. 2006]. We will see in Section 7.3 that $c = 0.8$ proposed in [Lowe 2004] by Lowe is able to guarantee good performance. It is worth noting that c is the only parameter to be set for this classifier considering that the similarity search performed over the local features in \mathcal{T}_l does not require a parameter k to be set.

Weighted LF Distance Ratio Classifier ($\hat{\Phi}^w$). The *Weighted LF Distance Ratio Classifier* is an extension of the *LF Matching Classifier* defined in the previous section. However, the confidence here is not binary but is a fuzzy measure derived from the distance ratio. Given that the greater the confidence the better the matching, we define the assigned label and the respective confidence as:

$$\nu(\hat{\Phi}_s^1, l_x) = (1 - \hat{\sigma}(l_x, \mathcal{T}_l))^2$$

The intuition is that it could be preferable not to filter non-matching features on the basis of the distance ratio, but to adopt $1 - \hat{\sigma}(l_x, \mathcal{T}_l)$ as a measure of confidence for the classification of the whole image. The value is then squared to emphasize the relative importance of greater distance ratios.

Please note that for this classifier, we do not have to specify either a distance ratio threshold c or k . Thus, this classifier has no parameters.

Weighted LF Distance Ratio with Geometric Constraints $\hat{\Phi}_g^w$. It is also possible to combine the classification approach of the *Weighted LF Distance Ratio Classifier* with the geometric consistency filtering power presented in Section 5.3.

First, we perform a nearest neighbor search for each local feature on the image I_i to be classified. At the end of this process, for each local feature $l_i \in I_i$, we apply geometric consistency filtering to obtain sets of candidate matches for $\langle I_i, I_j \rangle$ image pairs. Finally, we merge the local features pairs $\langle l_i, l_j \rangle$ in all the filtered matches \bar{M} , i.e.:

$$\mathcal{M}_g = \bigcup_j \bar{M}_g(I_i, I_j)$$

where g stands for *HOU* (Hough), *RST* (Rotation, Scale and Translation), *AFF* (Affine) and *HMG* (Homography) as explained in Section 5.3. Please note that I_j are at most all the images having at least one feature in $\bar{k}NN(l_i, \mathcal{T}_l) \forall l_i \in \mathcal{T}_l$. Furthermore, given that each geometric consistency filter requires a minimum number of points to be applied, the cardinality of I_j is typically much smaller.

The classification process is then performed as for the *Weighted LF Distance Ratio Classifier* just considering the filtered set of local features \mathcal{M}_g obtained with one of the specific filters (*HOU*, *RST*, *AFF*, or *HMG*), i.e., $\hat{\Phi}_s^1(l_x, \mathcal{M})$, and the following confidence:

$$\nu(\hat{\Phi}_s^1, l_x) = (1 - \hat{\sigma}(l_x, \mathcal{M}))^2$$

6.4.2 Step 2: Image Classification. In the following, we assume that the label of each local feature l_x , belonging to images in the training set \mathcal{T}_l , is the label assigned to the image to which it belongs (i.e., I_x):

$$\forall l_x \in I_x, \forall I_x \in T, \Phi(l_x) = \Phi(I_x) \quad (18)$$

In other words, we assume that the local features generated over interest points of images in the training set can be labeled as the image to which they belong. Note that the local features classifier can manage the noise introduced by this label propagation from the whole image to the local features. In fact, we will see that when very similar training local features are assigned to different classes, a

local feature close to them is classified with a low confidence. The experimental evaluation reported in Section 7.3 confirms the validity of this assumption.

As already stated, given $l_x \in I_x$, the classifier $\hat{\Phi}$ of step 1 returns both a class $\hat{\Phi}(l_x) = c_i \in C$ to l_x and a numerical value $\nu(\hat{\Phi}, l_x)$ that represents the confidence that $\hat{\Phi}$ has in this decision.

The whole image is classified, given the label $\hat{\Phi}(l_x)$ and the confidence $\nu(\hat{\Phi}, l_x)$ assigned to its local features $l_x \in I_x$ during the first phase, using a confidence-rated majority vote approach. We first compute a score $z(l_x, c_i)$ for each label $c_i \in C$. The score is the sum of the confidences obtained for the local features predicted as c_i . Formally,

$$z(I_x, c_i) = \sum_{l_x \in I_x, \hat{\Phi}(l_x) = c_i} \nu(\hat{\Phi}, l_x).$$

The label that obtains the maximum score is then chosen:

$$\hat{\Phi}(I_x) = \arg \max_{c_j \in C} z(I_x, c_j).$$

As measure of confidence for the classification of the whole image, we use the ratio between the predicted and the second best class:

$$\nu_{img}(\hat{\Phi}, I_x) = 1 - \frac{\arg \max_{c_j \in C - \hat{\Phi}(I_x)} z(I_x, c_j)}{\arg \max_{c_i \in C} z(I_x, c_i)}.$$

This whole image classification confidence can be used to decide whether the predicted label has a high probability to be correct.

7. EXPERIMENTAL EVALUATION

The aim of this performance analysis is to evaluate the classification effectiveness of the different strategies of kNN classification combined with various types of local features with and without geometric consistency checks.

7.1 Dataset, Ground Truth, and Experiment Settings

The dataset that we used for our tests is publicly available and composed of 1,227 photos of 12 monuments or cultural heritage related landmarks located in Pisa.

It was created during the VISITO Tuscany project ¹ and was also used in [Amato et al. 2010; Amato and Falchi 2010; 2011]. The photos have been crawled from Flickr, the well-known on-line photo service. The IDs of the photos used for these experiments together with the assigned label and extracted features can be downloaded from [pis 2011]. In the following we list the classes that we used and the number of photos belonging to each class. In Figure 1 we reported an example for each class in the same order as they are reported in the list below:

- (1) *Battistero* (104 photos) – the baptistery of St. John
- (2) *Camposanto Monumentale (exterior)* (46 photos)
- (3) *Camposanto Monumentale (portico)* (138 photos)
- (4) *Camposanto Monumentale (field)* (113 photos)
- (5) *Certosa* (53 photos) – the charterhouse

¹<http://www.visitotuscany.it/>

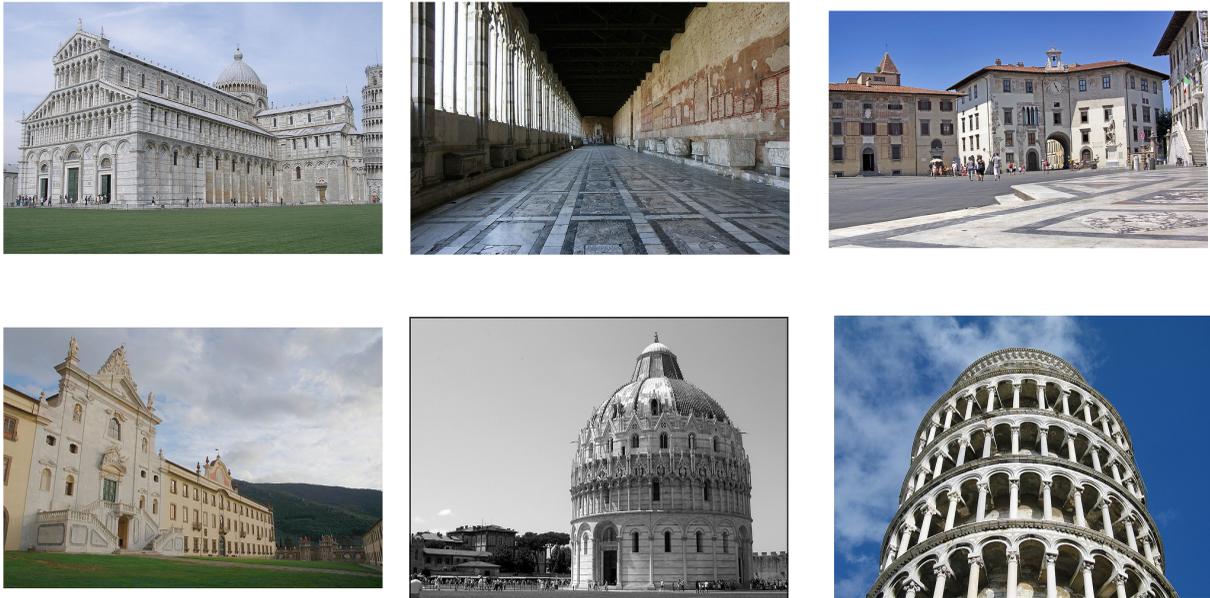

Fig. 1. Example images taken from the Pisa dataset (Images Available by Flickr under Creative Commons License agreement).

- (6) *Chiesa della Spina* (112 photos) – Gothic church
- (7) *Guelph tower* (71 photos)
- (8) *Duomo* (130 photos) – the cathedral of St. Mary
- (9) *Palazzo dell’Orologio* (92 photos) – building
- (10) *Basilica of San Piero* (48 photos) – church of St. Peter
- (11) *Palazzo della Carovana* (101 photos) – building
- (12) *Leaning Tower* (119 photos) – leaning campanile

In order to build and evaluate a classifier for these classes, we divided the dataset into a *training set* (\mathcal{T}_i) consisting of 226 photos (approximately 20% of the dataset) and a *test set* consisting of 921 photos (approximately 80% of the dataset). The image resolution used for feature extraction is the standard resolution used by Flickr (maximum 500 pixels for either the height or width)

The total numbers of local features extracted by the SIFT and SURF detectors were about 1,000,000 and 500,000 respectively. The number of local features per image varies between 113 and 2,816 for SIFT and 50 and 904 for SURF. ORB was tested setting the feature extractor to identify both 500 and 1000 local features. The number of local features detected for BRISK was less than 500.

Various classifiers were created using the local features taken into considerations and the definitions given in Section 6.

7.2 Performance Measures

In order to evaluate the effectiveness of the classifiers on the *test set*, we use the micro-averaged *accuracy* and micro- and macro-averaged *precision*, *recall* and F_1 .

In macro-averaging, the performance metrics are calculated for each class and then the average of all is evaluated. In micro-averaging, the average is calculated across all the individual classification decisions made by a system [Chau and Chen 2008].

Precision is defined as the ratio between the number of correctly predicted and the overall number of predicted documents for a specific class. *Recall* is the ratio between the number of correctly predicted and the overall number of documents for a specific class. F_1 is the harmonic mean of *precision* and *recall*.

Note that for the *single-label* classification task, micro-averaged *accuracy* is defined as the number of documents correctly classified divided by the total number of documents of the same label in the *test set* and is equivalent to the micro-averaged *precision*, *recall* and F_1 scores. Therefore, in the tables discussed in the following, we just report the values of *accuracy* and F_1 Macro.

7.3 Similarity Based Image kNN Classification Results

In Figure 2, we report the results obtained by both the local feature matching (see Section 5.1) and dataset matching (see Section 6.3). Given that the kNN classifier requires the parameter k , we report the results obtained for $k = 1$ (row labeled **k=1**), the best results obtained varying $k \in [1, 100]$ (row labeled **Best**), and the value k at which the best result was obtained (row labeled **Best k**). Figure 3 reports results obtained by using the BoW approach (see Section 5.2). The details are discussed in the following sections.

7.3.1 Local Feature Matching. Comparing the results obtained by the various similarity functions for the local feature matching comparison approach, we can see that geometric consistency checks are able to significantly improve the quality of the classification process. The best performance was generally obtained using the distance function that makes use of the affine geometric constraint. Only ORB with 500 local features and BRISK, sometimes obtain a better F_1 Macro, when using Rotation, Scale and Translation (RTS) geometric constraint checks. Overall, SIFT provides the highest effectiveness, achieving an *accuracy* and F_1 Macro of 0.94, with $k = 3$. However, ORB and BRISK have a more compact size and are easier to manage, given that they are binary features. Thus, even if their effectiveness is a little lower, their usage can be justified in terms of efficiency.

7.3.2 Dataset Matching. In Figure 2, we also report the results obtained by the dataset matching approach using $\bar{k} = 10$, i.e., performing a 10 nearest neighbors search for each local feature in the query over the local features in the training set. In our experiments, we also tested $\bar{k} = 30, 50$, and 100 obtaining comparable but worse results. We note that a peculiar feature of this approach is that it relies on spatial or metric access methods for similarity searching to significantly improve efficiency of classification with very large training sets. Notably this approach often performs better than the local feature matching approach. The intuition to justify this behavior is that the \bar{k} nearest neighbors search performed between all the local features in the training set is able to reduce the number of false matches. The best results are obtained using Hough and RTS geometric constraint checks, with an *accuracy* and F_1 macro of 0,95 and 0,94 respectively, using SIFT. Hough obtains the best performance using $k = 1$, RTS needs $k = 9$. As executing Hough transformation costs much less than RST, Hough is the best choice in this case. As previously, SIFT is the local feature that offers the best results in this case.

7.3.3 Bag of Words. In Figure 3, we report the results obtained by the BoW approach described in Section 5.2, using a vocabulary of $100k$ features selected using the k-means algorithm. As established in the literature, typically the more the words, the better the results. In our experiments, we are dealing with a dataset of about one million features. Thus, $100k$ of visual words is the highest value for which it

			Local feature matching					Dataset matching $\bar{k} = 10$				
			M_σ	Geometric consistency check				\bar{M}	Geometric consistency check			
				Hough	RST	Affine	Hom.		Hough	RST	Affine	Hom.

makes sense to perform a clustering algorithm. The results in this case are worse than those obtained with our proposed approaches discussed in Sections 7.3.1 and 7.3.2. In fact, both *accuracy* and F_1 Macro never exceed 0.9. Moreover, the geometric consistency checks do not significantly improve performance; this is particularly true for F_1 . The intuition is that the candidate matches found using the BoW approach are much too noisy. Standard cosine and TF-IDF similarity measures are more suitable for this scenario. It is worth noting that the k-means algorithm for selecting the $100k$ words was executed over the whole dataset, while it would have been more correct to only consider the training images. In fact, the test images should not be used during any training phase. However, we preferred to compare our approach in this scenario, even if the BoW performance is actually overestimated.

7.4 Local Features Based Image Classifier Results

Figure 4 reports the results obtained with the local feature based classifier (see Section 6.4). Similarly to the approach based on image to local features matching, this approach also allows us to signifi-

Fig. 3. Classification Results using the BoW approach with a vocabulary of 100k features.

cantly improve efficiency, relying on metric or spatial access methods for similarity searching. In fact, local features can be classified using distance functions that can be easily indexed using these access methods.

Experiments show that very good results are obtained even without geometric constraint checks. For instance, using SIFT, we obtained values of accuracy and F_1 Macro of 0.95 simply with the weighted local feature classifier. In just a few cases, Hough transformation slightly improves the performance. However, the improvement obtained does not justify the extra efficiency cost involved. For instance, for all binary local features, improvements range from 0.01 to 0.02 in both accuracy and F_1 Macro using Hough with respect to the simple weighted local feature classifier.

Overall, the performance of this approach is comparable to the best results obtained by the approach based on image to local feature matching. However, its efficiency is higher as it does not require geometric constraint checks to be performed.

Fig. 4. Local Features Based Classifier Results

In order to compare per class results, in Figure 5, 6, 7 and 8, we report the confusion matrices for the most relevant classifiers tested according to the results reported in the previous sections. All the results were obtained using SIFT in order to be comparable. We report actual classes by column and the assigned ones by row. Each monument is indicated by the number used in Section 7.1 for describing the dataset. The last rows show specific monument recall and F_1 Macro while in the last column we report the precision. The overall more difficult to recognize monuments resulted to be *Camposanto Monumentale* (2), *Certosa* (5), and *Guelph tower* (7). Comparing the matrices we see major variations on the relative and absolute performance obtained by the various approaches on (2) and (7). For instance, *dataset matching* (Figure 7) and *weighted LF Distance Ratio Classifier* $\hat{\Phi}^w$ (Figure 8) have overall similar performance but they obtained significant different results on these two classes.

8. CONCLUSIONS

In this paper, we have developed several strategies for efficient landmark recognition, which combine two different approaches to k -nearest neighbor classification applying different methods to match local descriptors.

The results of the experiments conducted in a cultural heritage scenario revealed that the approaches proposed gave a better performance than other state of the art approaches.

Among the techniques that we proposed, the local feature based classifier gave the best performance. With this classifier, we can improve efficiency by using metric or spatial access methods. In addition, the effectiveness provided is generally equal to or better than the other methods. The great advantage of this method is that it offers high performance even without geometric consistency checks, thus further raising efficiency. Comparisons were executed using various types of local features. The best performance was always obtained using SIFT. Although binary features (ORB and BRISK) were generally slightly worse, they can further boost efficiency, given their compactness and convenience for mobile applications.

A system built with the proposed image recognition approach is mainly intended to be used by visitors (tourists) of cities with cultural heritage related landmarks, for instance using a smartphone, to recognize and get information on monuments that they see. Clearly, these techniques can also be used to build systems to be used by researchers to retrieve information on artworks that are mainly described by their visual appearance. In this respect, we are using these techniques to provide access to databases of ancient inscriptions and epigraphy in the EU Funded EAGLE project [eag 2014]. The

traditional way of retrieving information from an epigraphic database is, for instance, that of submitting text queries related to place where the item has been found, or where it currently stored. Using our techniques, it is possible to retrieve information by simply using a picture of the epigraph as a query.
